(Dated: 20 February 2004)

We exhibit discrete memoryless quantum channels whose quantum capacity assisted by two-way classical communication, Q_2 , exceeds their unassisted one-shot Holevo capacity C_H . These channels may be thought of as having a data input and output, along with a control input that partly influences, and a control output that partly reveals, which of a set of unitary evolutions the data undergoes en route from input to output. The channel is designed so that the data's evolution can be exactly inferred by a classically coordinated processing of 1) the control output, and 2) a reference system entangled with the control input, but not from either of these resources alone. Thus a two-way classical side channel allows the otherwise noisy evolution of the data to be corrected, greatly increasing the capacity. The same family of channels provides examples where the classical capacity assisted by classical feedback, C_B , and the quantum capacity assisted by classical feedback Q_B , both exceed C_H . A related channel, whose data input undergoes dephasing before interacting with the control input, has a classical capacity $C = C_H$ strictly less than its C_2 , the classical capacity assisted by independent classical communication.

Introduction

Perhaps the most important open question concerning quantum discrete memoryless channels (DMCs) is whether, as is widely believed, the asymptotic classical capacity C is equal to the one-shot Holevo capacity C_H , defined as the maximum, over input distributions for a single use of the channel, of the entropy of the average output minus the average of the output entropies [1, 2]. Another open question is whether classical feedback can increase a quantum channel's classical capacity. For classical DMCs it has long been known that feedback does not increase the capacity, and Bowen et al [3] recently showed that this is also true for entanglement-breaking quantum DMCs, and for the entanglement-assisted classical capacity of any quantum DMC [4]. A related open question is whether there is any channel whose quantum capacity assisted by two-way classical communication Q_2 , or by classical feedback, Q_B , exceeds the unassisted classical capacity C . Here we exhibit channels for which C_B , Q_2 and Q_B all exceed C_H (and therefore C , if $C_H = C$).

To achieve these separations we use a special kind of quantum discrete memoryless channel which we call *retrocorrectable*. It may be thought of as having a data input and output, along with a control input that partly influences, and a control output that partly reveals, which of a set of unitary evolutions the data has undergone en route from input to output. The channel is designed so that the data's evolution can be exactly inferred by a classically coordinated processing of 1) the control output, and 2) a reference system entangled with the control input, but not from either of these resources alone. Thus a two-way classical side channel allows the data's otherwise noisy evolution to be corrected, greatly increasing

the capacity. These channels are described in section 1 and applied in sections 2 and 3.

The channels used in these constructions are not entanglement-breaking, and are not known to have $C = C_H$. However in section 4 we consider a weaker kind of retrocorrectable channel, in which the data input undergoes complete dephasing before interacting with the control input. These channels are entanglement-breaking by construction and therefore have $C_B = C = C_H$ and $Q_2 = 0$. Nevertheless, they have the nonclassical feature that their classical capacity is strictly less than their C_2 , the classical capacity assisted by two-way classical communication independent of the message to be transmitted. Section 5 discusses other results and remaining open questions concerning relations among the capacities.

1. The echo effect and retrocorrectable channels

Before introducing the class of channels that we will be using to prove capacity separations, we consider the underlying phenomenon in a simpler setting, that of a classic Bell-inequality experiment. In a typical such experiment, each member of a pair of polarization-entangled photons enters a separate analyzer which chooses randomly, and independently of the other analyzer, one of two nonorthogonal bases in which to measure the photon's polarization. The output of the analyzer is two classical bits indicating the basis b , and the result j of measuring the photon in that basis. The analyzer may be viewed abstractly as a quantum-classical (QC) channel taking a single quantum input to two classical outputs. Given such a two-output QC channel, we say that one of its outputs, here j , is externally *echoed* if it can be accurately inferred from the other output (here b) and

a system entangled with the channel input (in this case the other photon of the entangled pair), but could not have been accurately inferred had the input instead been a known unentangled pure state. The fact that supplying an input photon of known polarization is worse than supplying one with an entangled partner to be measured later is an essential manifestation of entanglement and the violations of Bell's inequality it gives rise to.

In our applications the externally echoed quantity, instead of being emitted as an output, is used internally within the channel to control the processing of another input. In more detail, we consider channels whose input and output spaces are each conceptually factorized into a control part and a data part. The channel performs a stochastic mapping of the data input variable onto a corresponding output variable, in a way that is partly influenced by the control input, and is partly revealed by the control output. The goal is to design the channel so that the stochastic mapping of the data variable can be corrected and made noiseless with the help of measurements on the control output and on a reference system entangled with the control input, but not by either resource alone. Two-way communication allows the measurements at the sending and receiving ends to be coordinated and exploited, thereby increasing the capacity above what could be achieved by any noninteractive protocol. Of course it is necessary to be sure that the control input and output do not, by their mere presence, increase the Holevo capacity so much as to neutralize the gains achieved by using them to correct the data variable's stochastic evolution.

Specifically we consider a family of channels, for integers $c, d \geq 2$, which we call *standard retrocorrectable channels* and denote $\mathcal{R}_{c,d}$. Their internal operation is depicted in Figure 1.

2. Holevo capacity and coherent information

Owing to the retrocorrectable channels' high symmetry, their one-shot Holevo capacity can be calculated assuming a uniform distribution over the data input and an arbitrary fixed value of the control input. The control outputs do not contribute to the Holevo capacity because they are uncorrelated with the input. In the $c = d = 2$ (qubit) case

$$C_H = 1 + (\pi^2/18 - 5/6)/\ln 2 = 0.5888 \quad (1)$$

If we allow c to increase slightly superlinearly with d (e.g. as $c = d \log^3 d$), the randomization of the data becomes more efficient for larger d , making C_H tend to zero as $d \rightarrow \infty$. This follows the fact that under these conditions, 1) all but an asymptotically vanishing fraction of the probability distribution of outcomes j is contributed

FIG. 1: The standard retrocorrectable channel $\mathcal{R}_{c,d}$ has a data input living in a d -dimensional Hilbert space, and a corresponding output; a control input living in a c -dimensional Hilbert space; and a classical control output living in a large Hilbert space. The channel internally selects a random basis B , for $\mathcal{H}_c$ and a set of c random unitaries $\{U\} = U_1 \dots U_c$ on $\mathcal{H}_d$. The channel measures the control input in the basis B , yielding result $j \in \{1 \dots c\}$. and according to that result applies one of the unitaries U_j to the data input, which is then emitted as the data output. The channel also emits a classical control consisting of the random basis B and the set of random unitaries $\{U\} = U_1 \dots U_c$. It does not, however, emit the measurement result j but keeps it hidden, or, in another way of speaking, discards it into the channel's inaccessible environment.

by outcomes of probability less than $1/(d \log^2 d)$ [5], and 2) except for these improbable outcomes, the application of an unknown unitary from a known set of random unitaries on $\mathcal{H}_d$ of cardinality $d \log^2 d$ constitutes an asymptotically randomizing quantum channel in the sense of Hayden et. al. [6].

The one-shot coherent information is similarly maximized by choosing a uniform ensemble for the data variable and a fixed value for the control variable. Although the one-shot coherent information may be only a lower bound on the unassisted quantum capacity for this channel, the latter is in any case bounded above by the unassisted classical capacity C , and so, if C_H is additive, by C_H . The maximal one-shot coherent information is 0.4262 for $c = d = 2$ and approaches zero for $d \rightarrow \infty$, if, as before, c is allowed to increase slightly superlinearly with d .

3. Assisted Capacities

By using the echo effect to retrospectively correct the otherwise noisy evolution of the data qubit, we can show that for appropriate choices of c and d , the retrocorrectable channel's channel's assisted capacities, C_B , Q_2 , C_2 , Q_E and C_E all can be made to exceed the one-shot

FIG. 2: Protocol for using the retrocorrectable channel $\mathcal{S} = \mathcal{R}_{2,2}$, in conjunction with two-way classical communication, to implement a noiseless qubit channel. Sender Alice is at the top, receiver Bob at the bottom. Alice feeds the control input half of a maximally entangled pair, whose other half she later measures in the basis B^T , after Bob has told her B through a classical back channel. This measurement, yields, via the “echo effect,” the same outcome j as occurred earlier within the channel. Alice tells Bob j through a forward classical channel, after which he can undo the unitary transformation U_j that the channel performed, restoring the data output qubit to the same state as it had initially.

Holevo capacity C_H . Indeed, by allowing c to increase slightly superlinearly with d as in the previous section, all the assisted capacities can be made to increase linearly with $\log d$, while C_H tends to zero.

Figures 2-5 show respectively how the channel $\mathcal{R}_{2,2}$ can be used

- to transmit a faithful qubit in the presence of two-way communication;
- to generate a faithful ebit in the presence of classical back communication; and
- to transmit a faithful qubit without back communication, but consuming an ebit previously shared between sender and receiver.

The essential trick, shown in Figure 2, is to feed the control input half of an ebit (a maximally entangled pair of qubits), and then to measure the other half in the basis B^T , thereby creating an echo of the measurement result j that had been obtained earlier but discarded within the channel. In figure 2, Alice performs this measurement after she has learned the value of B through the back channel. She then sends the measurement result to Bob, which allows him to correct the evolution of the data qubit, resulting in a faithful qubit.

Figure 3 shows how the channel $\mathcal{S}$ together with back communication can be used to create an ebit. Finally, figure 4 shows how the channel, in conjunction with an ebit shared earlier, can be used to implement a faithful forward qubit channel.

Continuing to use $\mathcal{S}$ to represent the standard retrocorrectable channel $\mathcal{R}_{2,2}$ of Figure 1, we have the following

FIG. 3: When used in conjunction with backward classical communication, the (2,2) retrocorrectable channel $\mathcal{S}$ can be used to generate an a standard maximally entangled pair of qubits. To do this, Alice feeds both inputs with halves of maximally entangled states. The auxiliary input’s reference system is used in conjunction with a classical back channel as before to learn the internal measurement outcome j through the echo effect. Alice then applies the unitary transformation U_j^T to the reference system entangled with the main input, thereby restoring the combination of it and the main output to a standard maximally entangled state.

FIG. 4: When used in conjunction with an ebit shared beforehand between Alice and Bob, the channel $\mathcal{S}$ can be used to generate a faithful qubit channel.

reducibilities.

$$1 \text{ ebit} \leq \mathcal{S} + \text{back communication} \quad (2)$$

$$1 \text{ qubit} \leq \mathcal{S} + 1 \text{ ebit} \quad (3)$$

These imply

$$1 \text{ qubit} \leq 2 \mathcal{S} + \text{back communication}$$

and, using superdense coding,

$$2 \text{ cbit} \leq 3 \mathcal{S} + \text{back communication}$$

These constructions may be extended to variable c and d , and, in the limit of large d with c increasing slightly

superlinearly with d , we have the following:

$$\lim_{d \rightarrow \infty} C_H = 0 \quad (4)$$

$$\lim_{d \rightarrow \infty} Q_2 = \log d \quad (5)$$

$$\lim_{d \rightarrow \infty} Q_B \geq \frac{1}{2} \log d \quad (6)$$

$$\lim_{d \rightarrow \infty} C_B \geq \frac{2}{3} \log d \quad (7)$$

The last two expressions are lower bounds, because it is possible (though we have no evidence for it) that a higher Q_B or C_B might be achieved by some other protocol than ours.

4. Other similar channels

Other simpler channels with nontrivial echo effects can be constructed. For example, consider a simplified (2,2) channel that measures its control qubit in a random one of two fixed conjugate bases and, according to result, either does or doesn't depolarize its data qubit input before emitting it as the data output. The control output is then a single classical bit indicating the measurement basis. While the limited control information does not allow the data variable's evolution to be corrected completely, it does allow depolarization events to be converted to less costly erasures, thereby creating a separation between Q_2 and C_H . The maximum Q_2 of $\cos^2 \frac{\pi}{8} = 0.85355$ is achieved by setting the control qubit midway between the $|0\rangle$ eigenstates of the two conjugate bases, while the maximum C_H of $\frac{1}{2} + \frac{1}{2}(1 - h_2(\frac{1}{4})) = 0.59436$ is obtained by setting it equal to the $|0\rangle$ eigenstate of one of them. This channel is the simplest example of what might be called a partially retrocorrectable channel.

The channels considered so far are not entanglement-breaking. To obtain an echo effect in an entanglement-breaking channel, we modify the standard (2,2) retrocorrectable channel $\mathcal{S} = \mathcal{R}_{2,2}$ by unconditionally dephasing its data input in the computational basis before applying the conditional unitary. Being entanglement-breaking, this channel can have no quantum capacity without entanglement assistance ($Q = Q_B = Q_2 = 0$), but it does have a C_2 capacity of 1, strictly greater than its Holevo capacity of 0.5888. Since it is entanglement-breaking, its C_B capacity must also equal the Holevo capacity, by the argument of Bowen and Nagarajan [3]. Therefore this channel definitely (without any assumptions about additivity of C_H) violates the second part of the equality $C = C_B = C_2$ obeyed by all classical DMCs.

5. Relations among capacities

Assuming for the remainder of this section the additivity of Holevo capacity, we can construct a ladder diagram

(Fig. 5) showing a double hierarchy with classical capacities $C \leq C_B \leq C_2 \leq C_E$ on one side and corresponding quantum capacities $Q \leq Q_B \leq Q_2 \leq Q_E$ on the other. Each quantum capacity is upper bounded by its corresponding classical capacity, and in every case but Q_E vs C_E , the inequality can be saturated. Here C_2 denotes a channel's classical capacity when assisted by an arbitrary classical two-way side conversation, subject only to the limitation that, taken as a whole, the side conversation be independent of the message being transmitted through the main protocol. With this restriction it is easy to show that $C_2 = C$ for any classical DMC, whereas without it the side conversation would become a short circuit making C_2 trivially infinite. It has not been customary to impose a similar independence restriction in the definition of Q_2 , where no short circuit problem exists. But in fact, without loss of generality, the classical side conversation in Q_2 can also be required to be independent of the (quantum) message being transmitted through the main protocol, because if it were not independent, it could be used as a means of eavesdropping on the quantum message without disturbing it. From another viewpoint, C_2 represents a channel's private classical capacity when assisted by two-way public communication, the adversary being given access to the side conversation but not the channel environment (cf [8]).

In passing, we note that attempting to define capacities such as " Q_{E2} " which would allow unlimited amounts of *both* shared entanglement *and* bidirectional classical communication, leads to a more serious short circuit problem, because independence does not prevent the assistive resources from being used for teleportation, making the capacity infinite.

Returning to Fig. 5, the general goal is to determine, for every pair of capacities, whether they are related by

- a strict inequality, as in the case of $Q_E < C_E$, with the inequality being saturated only trivially when both sides vanish;
- a saturable inequality as in $Q \leq C$; or
- an incomparability as between Q_E and C , in which, depending on the channel, either side may be greater.

The former two relations are indicated by a solid line in the ladder diagram, with the greater quantity being higher. Incomparability is indicated by a dashed line.

For each of the solid lines in Fig. 5, we need to find a proof of the general inequality and examples showing both equality and separation. Referring to the notes **a** through **h** in the diagram,

a: The general inequality $\leq$ can be shown by an argument involving monotonicity of the conditional mutual information (cf [7]). Equality is witnessed by the classical bit channel (ie a 100% dephasing qubit channel),

FIG. 5: Inequalities among capacities. A solid line denotes an inequality with the higher side being strictly greater than the lower side for some channels, but equal for other channels. A dotted line denotes an incomparability, where depending on the channel either capacity may be greater. The equalities in top left box follow from Bowen[4], along with teleportation and superdense coding. See text for comments labelled **a...l**. Question marks indicate instances where one or more aspects of the relation are conjectural.

for which it is easy to show that both capacities equal 1. Separation is witnessed by the noiseless qubit channel where we can show that $C_2 = 1$ but by superdense coding $C_E = 2$.

b: The general inequality follows from the fact that any protocol that achieves C_B can be modified to decouple the back communication from the message (cf [9]). Equality is witnessed by the classical bit channel, inequality by the dephased retrocorrectable channel of the previous section, for which $C_2 = 1$ but $C_B = C = C_H < 1$.

c: The general inequality is obvious. Equality holds for the classical bit channel, separation for the standard retrocorrectable channel (assuming $C = C_H$).

d: The general inequality is obvious. Equality holds for the qubit channel, separation for appropriate high dimensional retrocorrectable channels.

e: The general inequality is obvious. Equality holds for the qubit channel. We suspect but do not know how to prove that $Q_B < Q_2$ for channels such as $\mathcal{R}_{2,2}$. This separation would be implied by incomparability **k** which we also don't know how to prove.

f: The general inequality can be proved by a monotonicity argument similar to note **a** above. Equality is witnessed by the qubit channel, separation by channels such as the strongly depolarizing channel, for which Q_2 is zero but C and hence Q_E are positive.

g: These capacities are related by a constant factor of 2, making inequality strict unless both capacities vanish.

h: The general inequalities are obvious, from the fact that a qubit channel can simulate a bit channel. Separations are witnessed by the classical bit channel.

Turning now to the incomparabilities in Fig. 5,

i: $C_2 < Q_E$ may be witnessed by the $2/3$ depolarizing channel. This channel is known to have $Q_E > C_H$, and because it is unital, $C = C_H$. If we can show that $C_2 = C_H$ for this channel then we have a separation. The other separation $C_2 > Q_E$ is witnessed by the classical bit channel.

j: $C < Q_E$ is witnessed by $\mathcal{R}_{2,2}$ retrocorrectable channel (assuming additivity of C_H). $C > Q_E$ is witnessed by classical bit channel.

k: $C_B > Q_2$ is witnessed by classical channel for which $Q_2 = 0$. We conjecture that the retrocorrectable channel $\mathcal{R}_{2,2}$, with $Q_2 = 1$ and $C_B \geq 1/2$ witnesses the inequality in the other direction, but we do not have a nontrivial upper bound on C_B for this channel.

l: $C < Q_B$ holds for high dimensional retrocorrectable channels, assuming additivity of C_H . In the other direction, $C > Q_B$ is witnessed by the classical bit channel, for which $Q_2 = Q_B = 0$.
